Abstract

Objective: To assess the reliability and validity of body weight (BW) and body image (BI) perception reported by parents (in children) and by adolescents in a South American population.

Design: Cross-sectional study. BW perception was evaluated by the question, 'Do you think you/your child are/is: severely wasted, wasted, normal weight, overweight, obese?' BI perception was evaluated using the Gardner scale. To evaluate reliability, BW and BI perceptions were reported twice, two weeks apart. To evaluate validity, the BW and BI perceptions were compared with WHO BMI Z-scores. Kappa and Kendall's tau-c coefficients were obtained.

Setting: Public and private schools and high schools from six countries of South America (Argentina, Peru, Colombia, Uruguay, Chile, Brazil).

Participants: Children aged 3–10 years (*n* 635) and adolescents aged 11–17 years (*n* 400).

Results: Reliability of BW perception was fair in children's parents ($\kappa=0.337$) and substantial in adolescents ($\kappa=0.709$). Validity of BW perception was slight in children's parents ($\kappa=0.176$) and fair in adolescents ($\kappa=0.268$). When evaluating BI, most children were perceived by parents as having lower weight. Reliability of BI perception was slight in children's parents ($\kappa=0.124$) and moderate in adolescents ($\kappa=0.599$). Validity of BI perception was poor in children's parents ($\kappa=-0.018$) and slight in adolescents ($\kappa=0.023$).

Conclusions: Reliability of BW and BI perceptions was higher in adolescents than in children's parents. Validity of BW perception was good among the parents of the children and adolescents with underweight and normal weight.

Latin America is facing a rapid transition in the nutritional status of its populations, which has been characterized by an important increase in the prevalence of overweight and

obesity that affects all population groups, especially the youngest⁽¹⁾. The first step in preventing and treating obesity is to identify it. The correct perception of one's

*Corresponding author: Email laura.gonzalez@udea.edu.co

body weight can be a useful resource for the prevention and treatment of obesity⁽²⁾. This is one of the reasons for the increasing interest in body image perception in the field of health, especially in children and adolescents.

Body image has been defined by Schilder as 'the picture of our own body which we form in our mind'⁽³⁾. Gardner argues that body image includes two components: one perceptive, which refers to the estimation of size and appearance of the body; and another attitudinal, which collects feelings and attitudes towards one's body⁽⁴⁾. According to Baile, body image is a complex psychological construct which refers to how the self-perception of the body generates a mental representation composed of a body perceptive scheme, emotions, thoughts and associated behaviours⁽⁵⁾. The perceptual component implies the accuracy of the estimation of the body shapes the attitude and feelings towards the body⁽⁶⁾. Self-perception can be classified as correct, underestimated or overestimated, and this could generate body satisfaction or dissatisfaction. Some authors consider that perceptual distortion is the alteration of the perception manifested by an inability to accurately estimate the body size⁽⁶⁾.

Dissatisfaction with body image may be due, among other things, to social factors (media)^(7,8), culture⁽⁹⁾, friendships⁽¹⁰⁾, family⁽¹¹⁾ and psychological factors⁽¹²⁾. Throughout life, body image is in permanent (de)construction. A distorted perception of body weight or body image can trigger negative psychosocial consequences and unhealthy behaviours⁽¹³⁾. An overweight perception is associated with increased risk of developing low self-esteem, depression and anxiety, conditions that may lead to eating disorders, alcohol intake and cigarette smoking⁽¹³⁾. On the other hand, a person with overweight who perceives his/her weight to be normal may become detached from the situation and lose time in taking the right actions to avoid obesity (e.g. dieting and exercising)^(14,15).

Figure-rating scales are among the instruments most frequently used for assessing body image in children^(16,17). Gardner *et al.*⁽¹⁸⁾ developed a scale with thirteen figures in order to provide responders with enough options to choose from. They developed this instrument with constant increases among the figures through photography and video techniques, making them real and establishing a scale of analogous figures. Gardner's scale overcame limitations of previous ones by providing a major number of figures. In addition, the scale shows the figures' contour, avoiding race characteristics as hair and skin colour, making the instrument a reliable, valid and suitable scale to be used among different ethnic groups⁽¹⁸⁾.

In South America, several countries have validated different body image scales. In Brazil, a study carried out in adolescents of Florianópolis⁽¹⁹⁾ used a scale adapted from Childress *et al.* with eight figures⁽²⁰⁾ to evaluate body contour and correlate data for the contour identified by the child with the child's BMI Z-score. Results showed that both males and females with larger BMI Z-scores chose larger body contours. In Valparaíso,

Chile⁽²¹⁾, Body Silhouette Charts were applied and compared with the person's real BMI in order to evaluate body image and to establish a possible correlation between the perceived weight in the body image and the real nutritional status in students from 6 to 13 years of age. More females than males underestimated their weight (62.5 *v.* 52.5 %) and 98.1 % of the individuals with obesity underestimated their weight, while the same behaviour was observed in 100 % of the children with an overweight condition. In Bucaramanga, Colombia⁽²²⁾, the body image of adolescents was evaluated using the Gardner scale and the Standard Figural Stimuli, and the authors found good evidence of their validity and reliability when comparing with BMI.

In a recent review of the literature about body image in children, Neves *et al.*⁽²³⁾ found that the instrument used in 60.6 % of the studies reviewed was the silhouette scales. However, one of the main limitations was the use of non-validated collection instruments for the populations of interest. Most of the studies included in that review were carried out in the USA and Australia. In South America, Brazil is the country that has more publications, followed by Colombia and Chile. The authors recommended performing studies to create or validate scales for children, looking for a global understanding of infantile body image⁽²³⁾. At this point, to the best of our knowledge, there have been no multicentre studies comparing the reliability and validity of body weight and body image perception among children from South America.

Thus, the objectives of the present study in a South American population were to: (i) establish the reliability and validity of body weight perception reported by parents (in children aged 3–10 years) and self-reported by adolescents (aged 11–17 years); and (ii) establish the reliability and validity of a body image scale reported by parents (in children aged 3–10 years) and self-reported by adolescents (aged 11–17 years).

Materials and methods

Study design and participants

The South American Youth/Child Cardiovascular and Environmental (SAYCARE) Study is an observational, multicentre, feasibility study, which was carried out in seven South American cities (Buenos Aires, Lima, Medellín, Montevideo, Santiago, São Paulo and Teresina) designed to examine the reliability and validity of several nutritional, cardiovascular health, environmental, social and lifestyle methods. Six hundred and thirty-five children (3–10 years old) and four hundred adolescents (11–17 years old) were included in the analysis. A detailed description of the SAYCARE methodology has been published elsewhere⁽²⁴⁾.

A questionnaire about body weight and body image perceptions was completed by adolescents (11–17 years old) and children's parents (3–10 years old). Only those aged 11 years or older answered the questions

themselves. For the others, following the recommendation of Lanfer *et al.*⁽²⁵⁾, it was the parent/caregiver who answered the questions.

Sample size calculations were performed to test the reliability and validity of body weight perception and body image perception. For both analyses, the sample size was calculated using Cronbach's $\alpha = 0.65$, $\alpha = 5\%$ and $1 - \beta = 80\%$ ⁽¹⁸⁾. From these parameters, the necessary sample size estimated was 125 participants. Considering the possible loss of participants, a 20% larger sample size was recruited for these analyses ($n = 150$ for reliability).

Body weight was measured to the nearest 0.1 kg using a digital scale (WISO W801; Barreiros, Brazil). Height was measured to the nearest 0.1 cm using a stadiometer (Cardiomed WSC; Paraná, Brazil). Anthropometric measurements were done at least in duplicate; a third measurement was done when the difference between the first and the second measures was greater than 0.1 kg for body weight or 0.5 cm for height. Measurements were carried out by two trained anthropometrists following the standard techniques described by Lohman *et al.*⁽²⁶⁾.

Body weight perception was evaluated by asking to adolescents and children's parents the following question with five answer options: 'Do you think you/your child are/is: severely wasted, wasted, normal weight, overweight, obese?' For testing reliability, this question was asked twice, two weeks apart (T1 and T2). For validation of the body weight perception, the answers were compared with the WHO BMI classification for children and adolescents, which has five categories: severely wasted, wasted, normal weight, overweight and obese^(27,28).

The scale proposed by Gardner *et al.*⁽¹⁸⁾ was used to evaluate body image perception. This scale consists of thirteen silhouettes developed using data from the US National Center for Health Statistics. The central silhouette corresponds to the median weight in the National Center for Health Statistics growth chart; there are six silhouettes to the right that increase the weight by 5% each and six silhouettes to the left that decrease the weight by 5% each (Fig. 1(a)). In order to test reliability, the Gardner scale was applied twice, two weeks apart (T1 and T2). The thirteen silhouettes were also compared with BMI Z-scores for validation. The central silhouette matched the Z-score range between -0.50 and 0.50 ; in the six silhouettes to the right that increased by 0.5 Z-score units each and in the six silhouettes to the left that decreased by 0.5 Z-score units each (Fig. 1(b)).

In a subsequent analysis, the data of the thirteen silhouettes from the Gardner scale were classified into five groups to match the BMI classification. For children older than 5 years of age, the silhouettes labelled less than 80% were classified as severely wasted; silhouettes labelled 85 to 90% were classified as wasted; silhouettes labelled 95 to 105% were classified as normal weight; silhouettes labelled 110 to 115% were classified as overweight; and silhouettes labelled higher than 120% were classified as obese (Fig. 1(c)). For children who aged 5 years or

younger, the silhouette labelled 70% was classified as severely wasted; silhouettes labelled 75 to 80% were classified as wasted; silhouettes labelled 85 to 115% were classified as normal weight; silhouettes labelled 120 to 125% were classified as overweight; and the silhouette labelled 130% was classified as obese (Fig. 1(d)).

Statistical analyses

The SAYCARE questionnaire followed the universalistic methodology proposed by Herdman *et al.*⁽²⁹⁾. The reliability (test-retest reliability) between body weight perception and body image perception at two different times (T1 and T2) was evaluated using Kendall's tau-c coefficient. The inter/intra-instrument reliability was evaluated with Cronbach's alpha coefficient.

For validity, body weight perception and body image perception at T1 and the BMI classification data were analysed in the following two steps. First, weighted kappa coefficients (criterion validity) were interpreted according to Landis and Koch: κ values above 0.80 indicated almost perfect agreement, values between 0.61 and 0.80 indicated substantial agreement, values from 0.41 to 0.60 indicated moderate agreement, values from 0.21 to 0.40 indicated fair agreement, values between 0.00 and 0.20 indicated slight agreement, and κ values below 0.0 indicated poor agreement⁽³⁰⁾. Second, a receiver-operating characteristic curve was applied to calculate the predictive validity and accuracy of T1 to predict excess body weight (overweight and obesity). The receiver-operating characteristic curve provides the whole spectrum of specificity/sensitivity values for all the possible cut-offs. The area under the curve (AUC) is determined from plotting sensitivity *v.* $1 -$ specificity. Taking into account the suggested cut-off points, the test can be non-informative/test equal to chance; less accurate ($0.5 < AUC \leq 0.7$); moderately accurate ($0.7 > AUC \leq 0.9$); highly accurate ($0.9 > AUC < 1.0$); or perfectly discriminatory ($AUC = 1.0$)⁽³¹⁾.

The analyses were carried out in the statistical software packages IBM SPSS Statistics® for Windows, version 24.0 and Stata version 15.0. The criterion for statistical significance was a two-sided $P < 0.05$.

Results

The total sample included in the present study comprised 635 children and 400 adolescents; 51% were female. The mean BMI in both groups was appropriate for their age: 17.62 (SD 3.43) kg/m² in children and 21.62 (SD 3.95) kg/m² in adolescents, corresponding to a mean BMI-for-age Z-score of 0.72 (SD 1.22) and 0.55 (SD 1.10), respectively.

The numbers of adolescents and children's parents who answered the questions about body weight perception and body image perception appear in Fig. 2. The samples do not have the same size for both variables because some

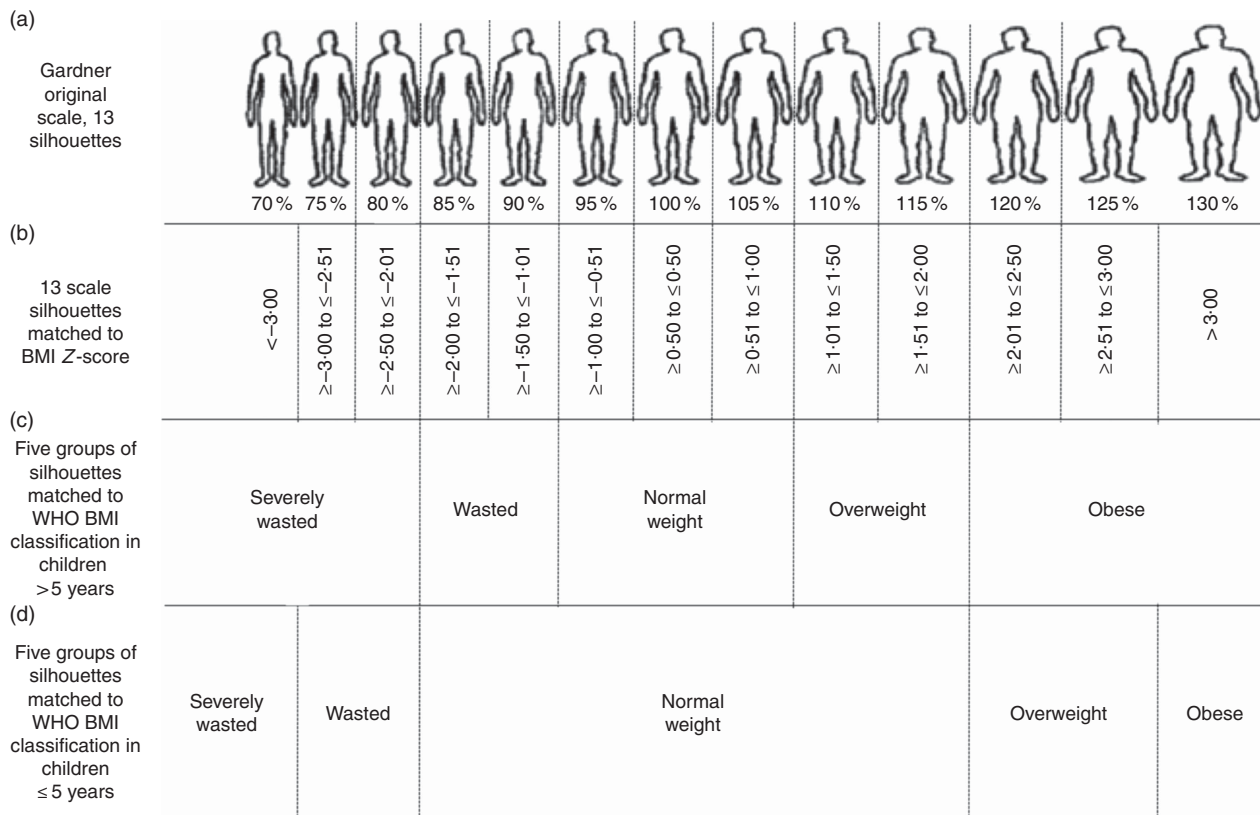

Fig. 1 Body image perception scale and matching BMI Z-score according to WHO classification: (a) Gardner's original scale, thirteen silhouettes⁽¹³⁾; (b) thirteen scale silhouettes matched to BMI Z-scores; (c) five groups of silhouettes matched to WHO BMI classification in children aged >5 years; (d) five groups of silhouettes matched to WHO BMI classification in children aged ≤5 years

of the participants did not respond to all the questions. A total of 442 parents and 272 adolescents answered the question about body weight perception at T1. The body image perception was evaluated among 421 parents and 248 adolescents who answered the question at T1. The number of participants decreased by T2 for both body image perception and body weight perception.

The reliability of body weight perception was fair ($\kappa=0.337$) among children's parents and substantial

($\kappa=0.709$) among adolescents (Table 1). The validity of body weight perception, when compared with BMI Z-score, was slight among children's parents ($\kappa=0.176$) and fair among adolescents ($\kappa=0.268$; Table 2). Among children's parents, validity of body weight perception was higher in those whose children were wasted (38.5%) and had normal weight (68.9%) than in those whose children were overweight (25.0%) or obese (15.7%; Table 2).

	$\tau_c = 0.305$ ($P < 0.001$); $\kappa = 0.176$ ($P < 0.001$)										$\tau_c = 0.343$ ($P < 0.001$); $\kappa = 0.268$ ($P < 0.001$)									

τ_c , Kendall's tau-c coefficient; κ , kappa coefficient.

The reliability of body image perception was slight ($\kappa = 0.124$) among children's parents and moderate ($\kappa = 0.599$) among adolescents (Table 3). Most of the children were perceived by their parents with silhouettes labelled 70 to 85%. Adolescents, on the other hand, perceived their body image with silhouettes labelled 90 to 110% (Table 3). The validity of body image perception, when compared with the BMI Z-score, was poor among children's parents ($\kappa = -0.018$; $P = 0.147$) and slight in adolescents ($\kappa = 0.023$; $P = 0.251$; data not shown).

When the results from the Gardner scale were classified in five groups to match the BMI classification, their reliability was fair among children's parents ($\kappa = 0.211$) and substantial among adolescents ($\kappa = 0.732$; Table 4). The validity of the five groups, when compared with BMI Z-score, was poor among children's parents ($\kappa = -0.011$; $P < 0.001$) and slight among adolescents ($\kappa = 0.083$; $P = 0.029$; data not shown).

Inter/intra-instrument reliability results for both age groups and both measurements (T1 and T2) showed a substantial stability of the administered tests and that the results were consistent. For children's parents, Cronbach's

$\alpha = 0.6386$ (T1) and 0.6687 (T2); for adolescents, Cronbach's $\alpha = 0.5949$ (T1) and 0.7687 (T2).

The results of predictive validity are shown in the online supplementary material, Supplemental Table 1. Body weight and body image perception for both age groups presented moderate accuracy ($AUC \geq 0.722$) to detect excessive body weight (overweight and/or obesity).

Discussion

According to the knowledge of the authors, the present study is the first multicentre one assessing the reliability and validity of body weight and body image perceptions among adolescents and children's parents in South America. Reliability of body weight perception was fair in children's parents and substantial in adolescents; validity of body weight perception was slight in children's parents and fair in adolescents. Reliability of Gardner's thirteen figures scale was slight in children's parents and substantial in adolescents; validity of the scale was poor in children's parents and slight in adolescents. After matching

Gardner's scale to the five BMI categories, the reliability improved in children's parents and adolescents; however, validity was still poor in children's parents and decreased in adolescents. The poor results in reliability and validity among children's parents can be due to multiple aspects. First is the fact that it was the parents who answered the questionnaires; a decision based on other studies indicating that before the age of 8 years the correlations between children's self-evaluations and their BMI are lower than in other age groups⁽¹⁷⁾. Second, the self-report methodology can be affected by the caregivers/parents' level of education; some studies suggest that with a lower level of parents' education there is more error in the selection of the silhouettes that estimate their children's weight^(32,33). Besides, there was a lack of control on who answered the questionnaires when they were sent to the children's houses, and the perception of the child's weight could be different if it was the mother or the father who answered the questionnaire⁽³³⁾. Finally, the use of Gardner's scale with thirteen silhouettes⁽¹⁸⁾ could have made difficult to choose the same figure at two different times.

The results for validity of body weight perception in children's parents were similar to those found in studies in Mexico⁽³⁴⁾ and Puerto Rico⁽³⁵⁾, confirming there is low validity between parents' perception of their child's weight and the child's real BMI ($\kappa=0.164$, Kendall's $\tau_c=0.124$). Similar reports were presented by other studies from Chile⁽³⁶⁾ and Mexico⁽³⁷⁾, where the authors concluded that parents of children with overweight have a distorted body image of them and tend to perceive them to be thinner than they really are. In the study from Mexico, it was also found that only a small proportion of mothers of children with overweight or obesity were able to perceive their child's weight correctly.

A study performed in Monterrey, Mexico⁽³³⁾ evaluated the BMI of 605 children and compared it with a scale of silhouettes. It found that 98.8% of parents underestimated the nutritional status of 161 children with overweight or obesity. This underestimation by the parents can be considered a risk factor for the development and/or maintenance of overweight and obesity. Another study from Mississippi, USA⁽³⁸⁾ concluded that the stronger predictor of obesity in children was the difference between the children's real BMI and the one perceived by their parents.

The poor results in terms of the validity of body weight and body image perceptions among children's parents can be due to the distortion between a child's real BMI and the one perceived by the parents, which seems to be modified by the child's nutritional status⁽³⁹⁾. In the present study, body weight and body image perceptions had higher validity among children with normal weight and the lowest validity was among children with obesity.

Reliability of body image perception through Gardner's scale was substantial. These results are contrary to those from a study carried out in Bucaramanga, Colombia⁽²²⁾, where the reliability of the Gardner scale was excellent

Table 4 Reliability of body image perception (Gardner's original scale, thirteen silhouettes⁽¹⁸⁾, regrouped into five groups) among parents of children (aged 3–10 years) and adolescents (aged 11–17 years) from public and private schools and high schools from six South American countries (Argentina, Peru, Colombia, Uruguay, Chile and Brazil); South American Youth/Child Cardiovascular and Environmental (SAYCARE) Study

(concordance of 0.93) among secondary-school students from public and private institutions. The differences in the results can be due to the facts that the questionnaires were applied differently, and also that the questionnaire was much longer in the present study, because, as mentioned before, the present study is part of a multicentre study that had different objectives; therefore, the participants' willingness to answer the questions in a trustworthy manner could have been affected.

The validity of the scale of silhouettes among adolescents was poor. The reliability improved after grouping the scales into five categories of BMI; however, the validity was still poor when compared with BMI Z-scores. The previous result could be explained by the difference between men's and women's ideal body image, which is conditioned by cultural, social and psychological aspects. The study from Valparaíso, Chile⁽²¹⁾ found poor concordance for the validity between nutritional status, perceived with a seven-figure scale, and real BMI. Those concordances oscillated between 0.031 and 0.275, similar to the values found herein.

The methodology of the studies on body image perception among children and adolescents is diverse, and so are their results⁽⁴⁰⁾. This could happen because the body image construct is complex and it is influenced by individual, family, cultural and contextual aspects, all of them determining the children's and adolescents' own perception of their body weight, as well as the parents' perception of their children's body weight. This represents an aspect to consider when developing health promotion programmes and illness prevention programmes, as it is necessary that parents recognize from the first stages of life what is the normal weight for their children in order to control and prevent malnutrition, especially overweight among children and adolescents. Reducing overweight and obesity is relevant because it has been found that overweight in childhood tends to remain during adult life and brings health risk factors, especially for CVD⁽³³⁾.

As a limiting condition, it is important to acknowledge that the present study used a convenience sample and therefore it is not representative. Finally, given that the study was carried out in seven cities from six countries, there could be sociocultural conditions that are expressed through a different perception of body weight and body image.

Conclusion

The present study results allow us to conclude that body weight and body image perceptions have a higher reliability among adolescents than among children's parents. Therefore, it is recommendable to perform studies comparing different methodologies of evaluation with children. The validity of body weight and body image perceptions compared with BMI Z-score was poor among

adolescents and children's parents. However, the validity of body weight perception was good when adolescents and children had normal weight or were wasted, and it was fair when both groups were overweight.

Acknowledgements

Acknowledgements: All authors acknowledge each school dean/chair, the children, adolescents and their respective parents for their voluntary participation in SAYCARE Study. In addition, they acknowledge Mr Andrew Mello Silva for management of the SAYCARE database. Colombia acknowledges the undergraduate students Carolina Alzate-Echeverri, Luisa Fernanda Arroyave-Zuleta, Sarah Ortiz-Calderón and Paola Zapata, for helping collect information and data entry; also nutritionist Juliana Diaz for helping with general processes. Uruguay acknowledges nutritionists Verónica Bauza, Iliana Carlini, Sofía Deveras, Stefani Izzi, Alejandra Olivera and Sofía Petingi for helping collect information and data entry. Argentina acknowledges the undergraduate students Sabrina Diaz, Lucina Bavosa and Julieta Vacarezza, and nutritionists Luciana Suca, Jesica Puca, Rocío Marcé and Candela Lepera, for helping collect information and data entry. **Financial support:** The SAYCARE Study was supported mainly by the Brazilian Government from the National Counsel of Technological and Scientific Development (CNPq; grant number 471266/2013-2) and the São Paulo State Government from the São Paulo Research Foundation (FAPESP; grant number 2014/11468-6). The SAYCARE Study was also co-funded by other agencies in the other countries: (i) the Collaborative Projects Fund (RD number 501-2015-INSN-DG-OEA) granted by the Instituto Nacional de Salud del Niño, Lima, Perú; (ii) the Sustainability Strategy at the University of Antioquia 2014–2015, Research Group of Social and Economic Determinants of Health and Nutrition, and Demography and Health Research Group at the University of Antioquia, Medellín, Colombia, and Interuniversity Services Corporation (CIS) from University of Antioquia; (iii) the Secretary of University Extension and Student Welfare, University of Buenos Aires, Buenos Aires, Argentina; and (iv) the European Regional Development Fund (MICINN-FEDER) to the GENUUD Research Group. The General Coordination of SAYCARE received several scholarships to develop the project: A.C.F.D.M. was given a postdoctoral scholarship from CNPq (grant number 313772/2014-2) and FAPESP (grant numbers 2014/13367-2 and 2015/14319-4). L.A.M. was given a scholarship as visiting professor from FAPESP

(grant number 2015/11406-3). H.B.C. is in receipt of an advanced scientist scholarship from CNPq (grant number 300951/2015-9). E.S. is in receipt of a doctoral scholarship from Carolina Foundation. **Conflict of interest:** None. **Authorship:** L.I.G.-Z., S.L.R.-M., J.C.A., E.S., T.S.C., L.B.A., W.V.N.-J., L.A.M., A.C.F.D.M., H.B.C. and A.E.-R. were involved in the data collection. L.I.G.-Z., S.L.R.-M., J.C.A., E.S., A.E.-R. and L.A.M. were involved in the conducting, analysis and writing of the manuscript. All authors were involved in writing the paper and had final approval of the submitted and published versions. **Ethics of human subject participation:** The study was performed according to the Declaration of Helsinki and was approved by the Bioethical Review Board of the Research System from the University of Antioquia, Medellín, Colombia (certificate number 14-43-596, 28 May 2014). Informed consent was obtained from all participants and guardians of the children.
